# Received for publication 24 May 1968

Mutant strains resistant to neomycin or to kanamycin sulfate were isolated from Escherichia coli K-12. Nine mutants were analyzed; all were resistant to both antibiotics (about 150 and 100  $\mu$ g/ml, respectively), and were designated *nek*. In the mutant strains, the ribosomes are changed from those of the parental strain; for when they were used in assays for polypeptide formation directed by polyadenylic acid or polycytidylic acid, coding fidelity in presence of the drugs was increased and inhibition of synthesis by the drugs was lessened. Mating experiments and transduction tests showed that all of the nine nek mutants are either closely linked or allelic, and the nek locus is closely linked to two genes-str (streptomycin) and spc (spectinomycin)—known to affect the 30S ribosome. The two nek mutants tested were recessive to the sensitive, wild-type allele. When the nek mutants were compared to the parental strain, pleiotropic effects of the nek mutations were observed. Resistance to low levels of streptomycin and spectinomycin was increased, whereas resistance to chloramphenicol was decreased. Also, the mutants were less able to adapt to high concentrations of lincomycin, and could no longer show phenotypic suppression of an arginine requirement by neomycin or kanamycin. Such pleiotropic effects are suggested to be the rule for mutations in genes that participate in the biosynthesis of a cellular organelle.

Because there appear to be at least 50 ribosomal proteins in *Escherichia coli* (9, 20), there is probably a comparable number of structural genes. Though it is not now clear whether any known mutation falls in a ribosomal structural gene (4), several approaches have permitted the isolation of mutants with altered ribosomes. One approach, exemplified here, involves the selection of mutants that are resistant to antibiotics that block protein synthesis.

Neomycin and kanamycin, like streptomycin, are aminoglycoside antibiotics. They share with streptomycin the ability to "cure" (i.e., pheno-typically suppress) certain mutations in strepto-mycin-sensitive strains (10, 22); again, like streptomycin, they lose this ability in strepto-mycin-resistant strains (5). These observations, as well as a study of an *E. coli* mutant (very likely a multistep mutant) resistant to kanamycin (17), suggested that mutants resistant to these antibiotics have modified ribosomes.

Strains resistant to neomycin or to kanamycin have been isolated; this paper presents the analysis of nine such mutants. All were resistant to both neomycin and kanamycin, and were mapped near the streptomycin locus. The strains tested had ribosomes that differed from those of the parental wild-type strains. These mutants have been designated *nek*.

#### MATERIALS AND METHODS

Genetic techniques and incorporation tests were as described previously (3, 4), except that the ammonium acetate wash of ribosomes was omitted.

In crosses between two *nek* mutants (*see* Results), the selective markers were chosen in such a way that the portions of the chromosome likely to bear the *nek* mutations would necessarily be included in the zygotes.

The levels of resistance to antibiotics were gauged by replicating colonies from broth-agar onto the same medium containing the relevant antibiotics. Selection of mutants was also carried out on broth-agar plates supplemented with antibiotics.

All antibiotics were commerically obtained, except for spectinomycin sulfate, which was a gift from G. B. Witfield, The Upjohn Co., Kalamazoo, Mich. Streptomycin sulfate was obtained from Eli Lilly & Co., Indianapolis, Ind., neomycin sulfate and lincomycin hydrochloride, from The Upjohn Co.; kanamycin Vol. 96, 1968

sulfate, from Bristol Laboratories, Inc., Syracuse, N.Y.; and chloramphenicol, from Parke, Davis & Co., Detroit, Mich. Different lots of chloramphenicol show bacteriostatic potency that varies by as much as a factor of 4; in general, the pure product, containing no additives, gives more reproducible results. For all lots, the relative resistance of various strains is the same. For all the other drugs tested, results were invariable from batch to batch.

## RESULTS

Isolation and characteristics of mutants. E. coli strains N141 or AB312 (see Table 1) were grown in broth, treated with N-methyl-N'-nitro-N-nitrosoguanidine (nitrosoguanidine), regrown in fresh medium for 4.5 hr, and plated on broth-agar containing different levels of neomycin sulfate or kanamycin sulfate or, as a control of the efficiency of mutagenesis, on broth-agar containing 200  $\mu g$  of streptomycin per ml. Wild-type strains, tested by replication, are resistant to about 5  $\mu g$  of streptomycin per ml, 5  $\mu g$  of kanamycin per ml, and 20  $\mu g$  of neomycin per ml. The highest concentrations of kanamycin and neomycin on which single-step mutants have been isolable are 100 and 150  $\mu$ g/ml, respectively. When either antibiotic was present at a concentration of 200  $\mu g/ml$ , no colonies were produced by a number of cells adequate to yield about 800 streptomycinresistant mutants. In several trials in which either 80  $\mu$ g of kanamycin per ml or 150  $\mu$ g of neomycin per ml was used, the spontaneous frequency of mutants resistant to kanamycin or neomycin was found to be very low, of the order of 10<sup>-11</sup>. This value is equivalent to about one-tenth the frequency of mutation to high-level streptomycin resistance, as determined by plating samples of the same culture on broth-agar plates containing 200  $\mu$ g of streptomycin per ml (see also 15).

All mutants isolated on either drug are resistant to both drugs, and have been therefore designated *nek* (for neomycin and kanamycin). The strains used in this work are listed and described in Tables 1-3.

*Pleiotropic effects.* Comparison of the *nek* mutants with the parent strain revealed three effects of the *nek* mutations.

(i) Changes in resistance to other antibiotics. Eight nek mutants were tested by replication for resistance to streptomycin and spectinomycin; all showed an increased resistance to streptomycin, and most also showed an increased resistance to spectinomycin (Table 3). However, the levels of resistance were much lower than those usually observed for mutants isolated as str-HR or spc<sup>r</sup> (5, 8, 15; also, cf. 17).

The resistance of *nek* mutants to several other antibiotics that affect ribosome function was also

checked. The nek mutants were no more resistant to lincomycin or erythromycin than the parental strains. However, they were appreciably more sensitive to chloramphenicol: wild-type strains withstand about 10  $\mu g$  of chloramphenicol per ml, but nek strains are able to resist less than 10  $\mu g/ml$  (Table 3). This characteristic of the nek mutants enables one to select a few  $nek^+$  cells from among a large population of nek cells. This was successfully done with all three nek mutants tried; the results with one of them, N733, are given in Table 4. The selection pressure is sufficient to permit the isolation of rare Nek-S (neomycinkanamycin sensitive) recombinants from a cross of two nek strains; the results obtained in one such cross are given in Table 5. In this cross of nek strains N743 and N751, portions of the mating mixture were plated either on medium that permitted growth of  $ad^+$  his<sup>+</sup> recombinants, or in the same medium supplemented with chloramphenicol. (Comparable numbers of the two strains were plated independently, but no revertants were found.) Colonies that grew on the medium containing chloramphenicol were streaked out; five colonies from each streak were tested for their characteristics. Most of the streaks gave rise to nek<sup>+</sup> colonies, identified by their wild-type sensitivity to neomycin and kanamycin. The frequency of recombination between the two unselected markers mal and argG was measured among a sample of  $ad^+$  his<sup>+</sup> recombinants (all Nek-R) and among an equivalent sample of  $ad^+$  his<sup>+</sup> nek<sup>+</sup> recombinants (50 colonies in each case). In the first instance, the recombination frequency was 28%; in the second, it was 37%. It therefore seems very likely that the  $nek^+$  colonies isolated in this cross are true recombinants.

(ii) Abolition of phenotypic suppression. In the parental strain N141, the arginine requirement can be replaced if the medium is supplemented by low, nonlethal levels of streptomycin, kanamycin, or neomycin (2  $\mu$ g/ml; these tests were carried out as described in reference 5). This phenotypic suppression (curability) by kanamycin and neomycin was lost in four *nek* mutants (N711, N712, N733, and N735), and was partially retained in the fifth mutant examined (N734). Phenotypic suppression by streptomycin was retained in three of these five *nek* strains, partially retained in N712, and abolished in N735 (see Discussion).

(iii) Lessened adaptability to lincomycin. Another difference between the response of nek strains and wild-type E. coli was observed in their response to phenotypic adaptation to high levels of lincomycin (4). Whereas the parental strain N141 adapted, growing up after about 24 to 48 hr, the nek mutants adapted only after a longer

TABLE 2. Genotypes of (nek) neomycin- and kanamycin-resistant strains<sup>a</sup>

<sup>a</sup> For symbols and parental strains, see Table 1.

<sup>b</sup> The parental strains resist about  $5 \mu g$  of kanamycin per ml and 20  $\mu g$  of neomycin per ml. All of the mutants are resistant, in replication on broth-agar plates, to about 100  $\mu g$  of kanamycin (Kan) per ml and 150  $\mu g$  of neomycin (Neo) per ml, and were initially isolated, after nitrosoguanidine treatment of the relevant parental strain, as colonies that grew on plates containing one or the other drug, as indicated.

<sup>a</sup> Tests were performed by replicating colonies from nutrient broth-Casamino Acids-agar onto the same medium supplemented with various concentrations of the antibiotics; plates were scored after 1 and 2 days. The numbers listed are the range of antibiotic concentration ( $\mu$ g/ml) at which colony formation is blocked.

<sup>b</sup> These two strains carry a str<sup>r</sup> allele.

lag of 3 to 5 days, or, in the case of one strain (N734), could not adapt at all (Table 6).

The mutation frequency of N734 to *lin* (high resistance to lincomycin; 4) was found to be about  $10^{-9}$ , reduced by a factor of  $10^3$  in comparison with the parental strain N141. This incompatibility of a *nek* mutation and *lin* mutations may be related to the failure of N734 to adapt to high levels of lincomycin.

Occurrence of altered ribosomes in nek mutants. Ribosomes from nek strains N711 and N733 were compared with those from the parental nek<sup>+</sup>

<sup>a</sup> Two strains were separately titered on minimal medium agar supplemented with all the requirements necessary for growth. Cells of the two strains were then mixed and plated together on the same medium supplemented with 20  $\mu$ g of chloramphenicol per ml, for the selection of *nek*<sup>+</sup> cells. Colonies growing on the plates supplemented with chloramphenicol were isolated (Cap-R) and streaked out, and some individual colonies from each streak were assayed for their genotype. AB774 was characterized by being Mal<sup>+</sup> and Nek-S; N733 was characterized by being Mal<sup>-</sup>

strain N141 in their response to artificial messenger ribonucleic acids (mRNA), including polyuridylic acid (poly U), polyadenylic acid (poly A), and polycytidylic acid (poly C). The results are summarized in Table 7.

All the experiments were run in duplicate and were repeated three to five times. The mean of each set of experiments with ribosomes from a mutant strain was compared to the relevant mean obtained with the ribosomes from the parental strain, in the t (Student) test, in order to gauge the

TABLE 5. Selection of nek<sup>+</sup> recombinants in a cross between two nek mutants<sup>a</sup>

<sup>a</sup> The cross was performed by "prolonged mating" (4). Portions were withdrawn, diluted, and plated on minimal medium plates supplemented with L-arginine and L-leucine (Ad<sup>+</sup> His<sup>+</sup> selection), or in the same medium with the addition of  $10 \mu g$  of chloramphenicol per ml (Ad<sup>+</sup> His<sup>+</sup> Cap-R selection). Colonies that grew up on plates containing chloramphenicol were streaked out on broth-agar and retested for their other characteristics.

TABLE 6. Adaptation of nek mutants to growth in presence of 1,000  $\mu g$  of lincomycin per ml<sup>a</sup>

N734	nek <sub>734</sub>	b
N735	nek <sub>735</sub>	3

<sup>a</sup> From cultures grown exponentially in broth, about 500 cells were inoculated into 10 ml of broth containing 1,000  $\mu$ g of lincomycin per ml; growth was recorded as positive when cultures showed turbidity corresponding to about 5 × 10<sup>8</sup> cells/ml. Colonies from the adapted cultures, if grown on medium lacking lincomycin, are once more indistinguishable from the original strains.

<sup>b</sup> Incapable of adapting; after 7 days, even the input cells were no longer recoverable.

probability that the two means represented determinations on samples of the same population (Table 7). When this probability was less than 0.05, it was concluded that the two means are significantly different. The primary conclusion from the results presented in Table 7 is that the ribosomes of the two *nek* strains tested are different from those of the parental strain. (In all experiments, changing the source of the supernatant enzymes did not change the results; one such set of experiments is presented in Table 7.)

The results given in Table 7 also indicate that, when poly U is the mRNA employed, mutant and wild-type ribosomes function with no significant difference. They are equally inhibited by drugs (Table 7), and also miscode for isoleucine to the same extent (*unpublished data*). When poly A is the messenger used, the ribosomes from *nek* mutants are significantly more resistant to the inhibition of lysine incorporation induced by neomycin, by kanamycin, or by streptomycin. When poly C is the mRNA, miscoded incorporation of histidine, threonine, or serine induced by neomycin or kanamycin is reduced in the nek strains.

Formal genetics of mutants. The nek mutations occur at a chromosomal site very closely linked to the well-known str and spc loci. This location was inferred from crosses of four nek mutants. For example, in the cross N709  $\times$  N302 (str<sup>\*</sup> nek  $\times$  spc<sup>r</sup>), of 54 spc<sup>r</sup> str<sup>r</sup> recombinants, 38 were nek. Similarly, in the cross N737  $\times$  N302 (str<sup>r</sup> nek  $\times$ spc<sup>r</sup>), among 161 str<sup>r</sup> spc<sup>r</sup> recombinants, 147 were nek, and of 145 spc<sup>r</sup> nek colonies isolated, all were str<sup>r</sup>. In the cross N53  $\times$  N711 (str<sup>r</sup> spc<sup>r</sup>  $\times$  nek), 100 ilv<sup>+</sup> thr<sup>+</sup> leu<sup>+</sup> recombinants were isolated, and among them the various classes of recombinants with respect to drug markers showed 7% recombination between the str and spc markers, 1% between str and nek markers, and 8% between the spc and nek markers. A similar result was obtained in the cross N53 imesN735 (str<sup>r</sup> spc<sup>r</sup>  $\times$  nek).

Close linkage of *nek* to the *str* and *spc* loci has been also confirmed in a series of transduction experiments. The results of one such experiment were as follows.

When N710 (*nek str<sup>r</sup> spc<sup>r</sup> mal*<sup>+</sup>) was the donor, and N141 (*nek*<sup>+</sup> str<sup>s</sup> spc<sup>s</sup> mal<sup>-</sup>) was the recipient, of 30 *nek* transductants, all were *mal*<sup>-</sup>, 20 were *spc<sup>s</sup> str<sup>s</sup>*, 4 were *spc<sup>r</sup> str<sup>r</sup>*, 4 were *spc<sup>s</sup> str<sup>r</sup>*, and 2 were *spc<sup>r</sup> str<sup>s</sup>*.

The close linkage of various *nek* mutations with the *str* and *spc* loci suggests that they all fall within a very small chromosomal region. Corroboration was obtained by direct tests in mating experiments. Each of the two *nek* Hfr strains (N709 and N737) was crossed with three different *nek* F<sup>-</sup> strains (N711, N733, N735). In each case, 224 *thr*<sup>+</sup> *leu*<sup>+</sup> *ilv*<sup>+</sup> *arg*<sup>+</sup> recombinants were selected; among all of these, only a single *nek*<sup>+</sup> recombinant was found (in the cross N709 × N735). A similar result was obtained with two other *nek* F<sup>-</sup> strains, in crosses of N709 × N712 and N737 × N734; in each case, 100 recombinants were analyzed, and only in the first cross was a single *nek*<sup>+</sup> recombinant colony detected. Thus, all

• The incorporation of each amino acid in presence of $20 \ \mu g$ of streptomycin (S), kanamycin (K), or neomycin (N) per ml is expressed as per- centage of the control incorporation without the drug (0) (mean values). Column 0 is given in counts per minute; the other columns list percentages. Experiments were repeated with different preparations of ribosomes. Most experiments were repeated three to five times, with the exception of poly C-directed serine incorporation for all the three strains, and poly U phenylalanine for strain N733, which were carried out only twice. To test for the significance of the differences, the means obtained with ribosomes of strains N711 and N733 were each compared with the corresponding mean for ribosomes of the parental strain N141, in a <i>t</i> test. The probability that the two means represent samples from the same population is listed in the last two lines. <i>P</i> values smaller than 0.05 are accepted to indicate significant differences between mutant and parental strain. Incorporation were directed by poly A, histidine, threonine, and serine incorporation were directed by poly C. The specific activity of the amino acids used were as follows: L-histidine, $164$ ; L-isoleucine, $160$ ; L-lysine, $187$ ; L-phenylalanine, $330$ ; L-serine, $87$ ; and L-threonine, $160$ (expressed in millicuries per millimole). The blanks, in counts per minute, for these amino acids were 55, $85$ , $95$ , $640$ , $63$ , and $104$ , respectively. These values were obtained by incubating mixtures identical to the experimental incubation mixtures, but lacking ribosomes. Although the results obtained depended on the source of the ribosomes, they were independent of the source of the supernatant factors used in the incorporation reaction. For example, two sets of results are given for poly A-directed lysine incorporation for strains N141 and N711; in the experiments reported in the first woo lines of the table, supernatant fluid from strain N141 was used; in the experiments reported in the fourth and fifth lines, supe	ration ration e repe e repe e repe rincor values values values values values repré e val	of eau ncorps ated w ated w aterorati erencati smalk smalk the ar ssed i ssed i ues we pendec the ta	the second secon	ino ac ino ac fiferent fiferent mean the mean the mean the mean the ino ac iouries a source results iperna	id in r put the put the put the put the put the r a r the r a r the r a r the r a r the r a r the r a r the r a r the r a r the r a r th	resence of the second strains strains strains strains strains strains strains istrains inlimol- ubating ubating ubating troi uid froi	e of 20 of ribo of ribo of ribo of ribo and p h ribo and p ribo and p ribo and p ribo and p ribo and p ribo and p ribo and p and p and p and p and p and p and p ribo and and p ribo and and and and and and and and and and	μg of s μg of s an value sonvalue soly U f soly U f thility t thility t thility t thility t thility t thility t thility t the sign screed by L-histi hey wei hey wei	was	to the second se	in (S), in 0 is g rementant of 11 an of 11 an of 11 an of 11 an of 11 an of 12 an of	no acid in presence of $20 \ \mu g$ of streptomycin (S), kanamycin (K), or neomycin (N) per ml is expressed as per- n without the drug (0) (mean values). Column 0 is given in counts per minute; the other columns list percentages. Freent preparations of ribosomes. Most experiments were repeated three to five times, with the exception of poly all the three strains, and poly U phenylalanine for strain N733, which were carried out only twice. To test for the means obtained with ribosomes of strains N711 and N733 were each compared with the corresponding mean for 141, in a <i>t</i> test. The probability that the two means represent samples from the same population is listed in the vylysine formation was directed by poly A; histidine, threonine, and serine incorporation were directed by poly C: vides used were as follows: L-histidine, 164; L-isoleucine, 160; L-lysine, 187; L-phenylalanine, 330; L-serine, 87; and icurcies per millimole). The blanks, in counts per minute, for these amino acids were 55, 85, 95, 640, 63, and 104, ained by incubating mixtures identical to the experimental incubation mixtures, but lacking ribosomes. seven *nek* mutations analyzed fall in a single locus. Two more *nek* mutants, N741 and N743, were subsequently analyzed and shown to be allelic (by the same criteria) with the seven *nek* mutants mentioned here.

Test for dominance. To see whether  $nek^+$  or nek is dominant, they were put into the same cytoplasm in a partial diploid. The  $nek^+$  allele was introduced from strain KLF41 into N711 ( $nek_{711}$ ) in one experiment, and into N735 ( $nek_{735}$ ) in a second. In each case,  $2 \times 10^7$  cells per ml of each parental strain were slowly agitated for 5 min at 37 C, and then left without further agitation for 25 min at 37 C. The mixture was then plated on basal medium containing maltose, L-isoleucine, L-valine, L-proline, L-arginine, L-histidine, and thiamine to select for colonies with the phenotype Mal<sup>+</sup> Leu<sup>+</sup> Met<sup>+</sup>. These recombinant colonies include both haploid cells and mero-diploids.

Among the Mal<sup>+</sup> Leu<sup>+</sup> Met<sup>+</sup> recombinants, colonies sensitive to neomycin and kanamycin were observed; a number were repurified by streaking on rich medium, and were then grown up in broth and restreaked on eosin methylene blue-maltose plates. Some of the colonies tested yielded Mal<sup>-</sup> segregants. A number of Mal<sup>+</sup> and Mal<sup>-</sup> colonies were then tested for resistance to neomycin and kanamycin, and colonies resembling the female parental strain were found. From a merozygote isolated from the cross KLF41  $\times$ N711, 23 Mal+ Nek-R, 73 Mal- Nek-R, 14 Mal+ Nek-S, and 3 Mal- Nek-S segregants were observed. Similarly, from a merozygote isolated from cross KLF41 × N735, segregants included 9 Mal<sup>+</sup> Nek-R, 57 Mal<sup>-</sup> Nek-R, 6 Mal<sup>+</sup> Nek-S, and 1 Mal- Nek-S colonies. Since both nek and  $nek^+$  alleles could be recovered in segregants of Nek-S partial diploids, it is concluded that the  $nek^+$  allele is dominant.

## DISCUSSION

The new locus described is located near the *str* locus of *E. coli* and affects ribosomes. The phenotypic characteristics of mutants in this locus suggest a general feature for mutations that affect ribosomes: pleiotropy. Here we discuss some of the effects of the mutations.

Effects of neomycin and kanamycin on protein synthesis in the mutants and the parental strain. As with most of the other known mutations that affect *E. coli* ribosomes, the in vitro difference between  $nek^+$  and nek strains in amino acid incorporation studies are relatively small, whereas in vivo differences between these strains are striking (cf. 4). Also, as observed for mutants to streptomycin resistance, in vitro tests with homopolymers exhibit sharper differences in miscoding, rather than in susceptibility to inhibition by the drugs (Table 7). The binding site for streptomycin is probably distinct from that for neomycin and kanamycin, since the mutations to resistance to the drugs fall in genetically distinct loci. However, the two sites must either overlap physically, or else a change in one site must distort the other, since, for example, mutations to streptomycin resistance abolish phenotypic suppression by all three drugs. Also, *nek* mutations confer limited resistance to streptomycin as well (Table 3).

In some instances, the effects in vitro parallel those in vivo. For example, streptomycin only partially inhibits polyphenylalanine synthesis on ribosome from a sensitive strain, even at very high drug concentrations, and this inhibition is totally alleviated in resistant strains; cultures of str-HR mutants withstand any measurable level of streptomycin. In contrast, comparable levels of neomycin and kanamycin block polymerization of phenylalanine and lysine nearly totally both in extracts of  $nek^+$  and of  $nek^-$  strains (Table 7): even the small remaining incorporation can be abolished by higher levels of drug (unpublished data), and nek strains acquire only limited resistance to either neomycin or kanamycin. Another example of parallelism in vitro and in vivo is provided by the miscoding induced by antibiotics when the messenger is poly C. While this miscoding is significantly reduced in the nek strains N711 and N733 in the presence of neomycin or kanamycin, the miscoding is not significantly reduced in the presence of streptomycin (Table 7). In a comparable way, in vivo in these two strains, neomycin and kanamycin cannot give phenotypic suppression, but streptomycin does (see Results). However, the parallels in vivo and in vitro may be fortuitous, as it is not clear to what extent inhibition or miscoding in protein synthesis directed by a homopolymer is a relevant index for the sensitivity of cells to drugs.

The effects of neomycin and kanamycin are probably exerted through an effect on 30S ribosomes, for there is (i) tight linkage of the *nek* locus to other genes which are known to affect the 30S ribosomes, the *str* and *spc* loci (6–8); (ii) cross-resistance of *nek* mutants to streptomycin; and (iii) similar behavior of neomycin, kanamycin, and streptomycin in phenotypic suppression.

Genetic analysis. The crosses and transduction data support the claim that all of the nine *nek* mutations tested are closely linked, and that the *nek* locus is closely linked to the *str* and *spc* loci. We conclude that it is less than 1 min from these loci, assuming that *I* time unit = 20 recombination units = 10% contransduction frequency. This correlation is constructed from data pub-

lished previously (12, 19). The relationship is definitely adequate, at least to a first approximation, since all of the data obtained in experiments with other markers in this chromosomal region are consistent with it. The linkage data presented in this paper concerning the *str*, *nek*, and *spc*, loci suggest that they are located in this order. However, the data are not conclusive.

*Pleiotropic effects.* Pleiotropy should be the rule rather than the exception for mutations that affect an organelle such as the ribosome, both because a ribosomal protein must interact with a variety of other proteins and with ribosomal RNA to form the structure, and because the resultant structure has to function in the precise and elaborate way required for accurate protein synthesis. Thus, the better-known cause for pleiotropy in bacteria, polar mutations in operons, is not a prerequisite for pleiotropy caused by mutations in genes that affect ribosomes.

In the other reported case in which mutants in the same locus confer a drastically changed response to two antibiotics, the lir locus, not all the mutants shared the property [sensitivity to either lincomycin or erythromycin (4)]. In the present case, however, all of the nek mutant strains tested resist both of the antibiotics. This might result if the ribosomal binding sites of these two antibiotics overlap completely, in contrast to those of lincomycin and erythromycin which do not. Alternatively, the nek mutations occur only at the overlap of the ribosomal binding sites for neomycin and kanamycin. The rarity of the nek mutations might result from such a limitation. In agreement with the second alternative is the fact that lower-level resistant mutants have been isolated that show increased resistance only to one drug or the other (unpublished data).

The fact that nek strains, unlike the parental strain, adapt very poorly to high concentrations of lincomycin is of particular interest. It has been unclear whether adaptation to lincomycin occurs through a change in the ribosome, or through some other process, such as a decrease in cell permeability to the drug. Since nek mutations have no obvious direct effect on cellular components other than the ribosome, the loss of adaptability in nek mutants supports the idea that adaptation involves a modification in the ribosome, possibly comparable to the one observed in ribosomes isolated from anaerobic cultures (12). Another possible case of adaptation through a change in the ribosome is the "phenotypic masking" described by Gorini, Rosset, and Zimmermann (11).

Perhaps the most interesting and useful of the observed pleiotropic effects is the increased sensitivity of *nek* mutants to chloramphenicol. The *nek* mutants probably affect the 30S ribosome, but chloramphenicol binds specifically to the 50S ribosome (21; Monro and Staehelin, *personal communication*). Thus, a mutation in one ribosomal particle may indirectly affect the function of the other particle.

The increased sensitivity of the *nek* strains to chloramphenicol permitted a reconstruction experiment (Table 4), in which a few  $nek^+$  (sensitive) cells were selected from among a large number of *nek* (resistant) cells. This finding opened the way for the fine genetic analysis of the *nek* locus and made possible a "two-way selection" (1, 2) for a gene that affects the ribosome. Crosses between pairs of *nek* mutants have been performed, and indeed *nek*<sup>+</sup> recombinants have been obtained (Table 5).
